Jolie Static Type Checker: a Prototype

de Carvalho D., Mazzara M., Mingela B., Safina L., Tchitchigin A., Troshkov N.

Received September 8, 2017

Abstract. Static verification of a program source code correctness is an important element of software reliability. Formal verification of software programs involves proving that a program satisfies a formal specification of its behavior. Many languages use both static and dynamic type checking. With such approach, the static type checker verifies everything possible at compile time, and the dynamic one checks the remaining. The current state of the Jolie programming language includes a dynamic type system. Consequently, it allows avoidable run-time errors. A static type system for the language has been formally defined on paper but lacks an implementation yet. In this paper, we describe a prototype of Jolie Static Type Checker (JSTC), which employs a technique based on a SMT solver. We describe the theory behind and the implementation, and the process of static analysis. The article is published in the authors’ wording.

Keywords: microservice, static analysis, Jolie programming language

1. Introduction

The microservice architecture is a style inspired by service-oriented computing that promises to change the way in which software is perceived, conceived and designed [17]. The trend of migrating monolithic architectures into microservices to reap benefits of scalability is growing fast today [7, 5]. Jolie [20] is the only language natively supporting microservice architectures [9] and, currently, has dynamic type checking only.

Static type checking is generally desirable for programming languages improving software quality, lowering the number of bugs and preventing avoidable errors. The
idea is to allow compilers to identify as many issues as possible before actually run the program, and therefore avoid a vast number of trivial bugs, catching them at a very early stage. Despite the fact that, in the general case interesting properties of programs are undecidable [26], static type checking, within its limits, is an effective and well established technique of program verification. If a compiler can prove that a program is well-typed, then it does not need to perform dynamic safety checks, allowing the resulting compiled binary to run faster.

A static type system for Jolie has been exhaustively and formally defined only on paper [25], but still lacks an implementation. The obstacles of programming in a language without a static type analyzer have been witnessed by Jolie developers, especially by newcomers. However, implementing such system is a non trivial task due to technical challenges both of general nature and specific to the language. In this paper, we introduce and describe the Jolie Static Type Checker (JSTC), building on top of the previous work on the Jolie programming language [20]. Our approach follows the formal derivation rules as defined in [25]. The project is built as a Java implementation of source code processing and verification via Z3 SMT solver [21] and it has to be intended as our community contribution to the Jolie programming language [2].

Section 2. recalls the basic of Jolie and section 3. discusses related work. The description of the static type-checking and the system architecture can be found in Section 4., while Section 6. draws conclusive remarks and discusses open issues.

2. Background

Microservices [6] is an architectural style evolved from Service-Oriented Architectures [12]. According to this approach, applications are composed by small independent building blocks that communicate via message passing. These composing parts are indeed called microservices. This paradigm has seen a dramatic growth in popularity in recent years [24]. Microservices are not limited to a specific technology. Systems can be built using a wide range of technologies and still fit the approach. In this paper, however, we support the idea that a paradigm-based language would bring benefit to development in terms of simplicity and development cost.

Jolie is the first programming language constructed above the paradigm of microservices: each component is autonomous service that can be deployed separately and operated by running in parallel processes. Jolie comprises formally-specified semantics, inspired by process calculi such as CCS [18] and the $\pi$-calculus [19]. As for practical side, Jolie was inspired by standards for Service-Oriented Computing such as WS-BPEL [34] and the attempts of formalizing it [13]. The composition of both theoretical and practical aspects allows Jolie to be the preferred candidate for the application of modern research methodologies, e.g. runtime adaptation, process-aware web applications, or correctness-by-construction of concurrent software.

The basic abstraction unit of Jolie is the microservice [6]. It is based on a recursive model where every microservice can be easily reused and composed to obtain, in turn, other microservices. Such approach allows distributed architecture and guarantees simple management of all components, which reduces maintenance and development effort. Microservices communicate and work together by sending messages to each other. In
Jolie, messages are represented in tree structure. A variable in Jolie is a path in a data tree and the type of a data tree is a tree itself with the same shape but containing types of corresponding data. Equality of types must therefore be handled with that in mind. Variables do not require declaration before use, therefore the manipulation of the program state must be inferred. Communications are type checked at runtime, when messages are sent or received. Type checking of incoming messages (at runtime?) is especially relevant, since it could moderate the consequences of errors.

The Jolie language is constructed in three layers: the behavioural layer operates with the internal actions of a process and the communication it performs as seen from the process’ point of view, the service layer deals with the underlying architectural instructions and the network layer deals with connecting communicating services.

Other workflow languages are capable of expressing orchestration of (micro)services the same way Jolie can do, for example WS-BPEL [34]. WS-BPEL allows developers to describe workflows of services and other communication aspects (such as ports and interfaces), and it has been also shown how dynamic workflow reconfiguration can be expressed [15]. However, WS-BPEL has been designed for high-level orchestration, while programming the internal logic of a single micro-service requires fine-grained procedural constructs. Here Jolie works better.

3. Related work

The implementation of a static type checker for Jolie is part of a broader attempt to enhance the language for practical use. Previous work on the type system has been done, however focusing mostly on dynamic type checking. Safina extended the dynamic type system as described in [28], where type choices have been added in order to move computation from a process-driven to a data-driven approach.

The idea to integrate dynamic and static type checking with the introduction of refinement types, verified via SMT solver, has been explored in [31]. The integration of the two approaches allows a scenario where the static verification of internal services and the dynamic verification of (potentially malicious) external services cooperates in order to reduce testing effort and enhancing security.

The idea of using SMT Solvers for static analysis, in particular in combination with other techniques, has been successfully adopted before for other programming languages, for example LiquidHaskell and F*. LiquidHaskell [11] is a notable example of implementation of Liquid Types (Logically Qualified Data Types) [27]. It is a static verification technique combining automated deduction (SMT solvers), model checking (Predicate Abstraction), and type systems (Hindley-Milner inference). Liquid Types have been implemented for several other programming languages. The original paper presented an OCaml implementation. F* [36] instead an ML-like functional programming language specifically designed for program verification. The F* type-checker uses a combination of SMT solving and manual proofs to guarantee correctness.

Another direction in developing static type checking for Jolie is creating a verified type checker² by means of proof assistant instead of SMT solver [1]. Proof assistant

2 [https://github.com/ak3n/jolie](https://github.com/ak3n/jolie)
is a software tool needed to assist with the development of formal proofs by human-machine collaboration and helps to ascertain the correctness of them. The type checker is expressed as well-typed program with dependent types in Agda [35]. If the types are well formed, all required invariants and properties are described and expressed in the types of the program meaning that the program is correct. This work is currently in progress and evolves in parallel with ours.

4. Static type-checking implementation

This paper builds on top of Julie Meinicke Nielsen’s work [25] at the Technical University of Denmark implementing the type system of the Jolie language. The thesis represents the theoretical foundation for the type checking of the core fragment of the language, which excludes recursive types, arrays, subtyping of basic types, faults and deployment instructions such as architectural primitives. The work of Nielsen presents the first attempt at formalizing a static type checker for the core fragment of Jolie, and the typing rules expressed there are the core theory behind our static checker.

In Nielsen’s work typing rules are represented in the style of type theory where the rules take form of inference rules describing how a type system assigns a type to a syntactic construct of the language [4]. Important addition to classical inference rules is that we use typing context $\Gamma$ both left and right of a turnstile. This accounts for Jolie-specific possibility to extend a variable’s inferred typing tree while analyzing program text which is rooted in dynamic nature of the language. The rules are then applied by the type system to determine if a program is well typed or not. The main typing rules will be presented in the following of this paper.

The implementation of JSTC consists of two system components. Firstly, a Java program accepts the source code of a Jolie program, builds an abstract syntax tree (AST), visits it and produces a set of logical assertions written in SMT Lib [3] language. At the second phase, the generated assertions are feed into Z3 solver. The basic idea is to implement, for each Jolie node\(^3\), methods containing statements expressed in the SMT Lib syntax. These statements can then be processed via a solver. In Figure 1 the overall process is pictorially represented and details are described in section 4.4.

The concept of SMT solvers is closely related to logical theorems. Logic, especially in the field of proof theory, considers theorems as statements of a formal language. Existence of such logical expressions allows to formulate a set of axioms and inference rules to formalize the typing rules for each of Jolie syntax nodes and then perform the validation of the nodes using constructed theorems. Consequently, the Jolie typing rules are the specific cases of logical theorems, that are used in the project. The concept is implied from software verification fundamentals [10].

Since Jolie program may contain complex expressions with function calls, it is also necessary to consider data structures representing a match between names and expressions, in order to be able to avoid inconsistency and redundancy, that are likely to cause conflicts during type-checking. The project implementation considers using a stack during the recursive checking of the nodes as illustrated in section 4.4.

\(^3\)Any syntax unit is considered a node. It can be a logical or arithmetic expression, an assignment; a condition; a loop etc. Those nodes comprise the abstract syntax tree.
The decision of using an SMT-solver, instead of more lightweight techniques, was made in order to allow a future straightforward integration of Refinement Types into the type checker, objective on which our team is already working [28, 31]. Furthermore, relying on a solid existing technology allowed us to prototype and release a proof of concept of the type checker in a shorter period of time.

4.1. Jolie verifier

The Java program reuses an existing structure of a Visitor pattern developed for Jolie interpreter and also used in a previous project for formatting Jolie source code\(^4\). It accepts processed Jolie program source code in the form of AST and performs traversing. For each kind of node the system creates one or more logical formulas written in SMT Lib syntax, which are then stored into a file\(^5\). The verifier targets assignments, conditions, and other cases of variables usage where type consistency can be violated.

4.2. SMT Solver

Z3 carries out the main burden of program verification. Z3 is an SMT solver from Microsoft Research [21]. It is targeted at solving problems that arise in software verification and software analysis. Given a set of formulas that was previously created by the verifier in Java, Z3 processes it and returns whether this set is satisfiable or not. In case of any contradiction in the set, the solver will signal that the overall theorem is not satisfiable, therefore alerting that the input program is not consistent in terms of types usage.

\(^4\)https://github.com/nickaleks/jolie
\(^5\)At the current implementation state the theorems are collected in a single data element.
4.3. Typing rules

Our objective is to accurately translate Jolie typing rules into SMT statements, therefore allowing static type checking\(^6\). The foreground activity so far is producing the set of statements for the constructs of the behavioural layer of Jolie. The layer describes the internal actions of a process and the communications it performs as seen from the process’ point of view. The layer is chosen for the first phase of the development because it forms foundation of the syntactical structures of Jolie. Also there is a similarity of the layer with common programming languages in a sense of the abstraction level.

All statements at the behavioural layer of Jolie are called behaviours. We write \( \Gamma \vdash_B B \triangleright \Gamma' \) to indicate a behaviour \( B \), typed with respect to an environment \( \Gamma \), which updates \( \Gamma \) to \( \Gamma' \) during type checking [25]. The context \( \Gamma \) consists of variables known to the type checker so far and their respective types.

There are some core rules presented and described below.

\textbf{T-Nil.} The typing rule for a nil behaviour is an axiom. In the conclusion the typing environment is not changed, since the nil statement doesn’t affect the typing environment.

\[
\Gamma \vdash_B 0 \triangleright \Gamma
\]

\textbf{T-If-Then-Else.} The rule for typing an if statement is standard: an if statement is typeable if its condition has type bool, and the type checking of its branches perform the same updates to the environment. We require the branches to perform the same updates because we do not know which branch will be taken. The else part may also be omitted and \( B_2 \) may be replaced by an empty behaviour. The conditional typing statement is the following:

\[
\Gamma \vdash e : \text{bool} \quad \Gamma \vdash_B B_1 \triangleright \Gamma' \quad \Gamma \vdash_B B_2 \triangleright \Gamma'
\]

\[
\Gamma \vdash_B \text{if}(e) \ B_1 \ \text{else} \ B_2 \triangleright \Gamma'
\]

\textbf{T-While.} The rule for typing a while statement is also standard: a while statement is typeable if its condition has type bool, and type checking its body has no influence on the typing environment.

\[
\Gamma \vdash e : \text{bool} \quad \Gamma \vdash_B B \triangleright \Gamma
\]

\[
\Gamma \vdash_B \text{while}(e) \ B \triangleright \Gamma
\]

Above, it is required that the body of a while loop does not change the typing of variables because we do not know whether the body will be executed at all, and for how many times. We also require that expression \( e \) is type checked against type bool.

\textbf{T-Seq.} A sequence statement typed with respect to an environment is typeable if its first component is typeable with respect to the environment and its second component is typeable with respect to the update of the environment performed by the first component. The update of the environment performed by the sequence statement is the update performed by the second component with respect to the update performed by the first component.

\(^6\)Please note that, at the moment, not all the rules in [25] have been implemented.
Thus, fundamental typing rules of the behavioural layer of Jolie programming language are presented and explained for further topic revelation.

4.4. Typing rules to SMT translation

Here we will examine an example of the conditional rule translation in order to understand the procedure in detail.

The typing rule of the if statement does not contradict intuition. The statement is typeable when its condition expression is boolean, and the execution of both its branches brings the same updates to the environment. This means that the set of matches between expressions and variables with their types remains the same with no difference from a branch choice. This is necessary since it is not possible to predict what branch will be executed at runtime\(^7\).

The full implementation is available on Github\(^8\). In Figure 2 we show the Java fragment that builds the corresponding SMT statement.

![Code in Java for checking conditionals](image)

Fig 2. Code in Java for checking conditionals

The code structure represents basic steps to achieve a record with corresponding SMT statements of the block as a result. Firstly, a condition of the if statement is separated from the body. Then the condition is sent to be checked using the same visitor class. Eventually after the last ‘recursion’ step the condition is put in the stack of terms, which contains any terms (expressions, variables etc.) processed during the checking. So

\(^7\)The else part may also be omitted and \(B_2\) may be replaced by an empty behavior.

\(^8\)https://github.com/innopolis-jolie-smt-typechecker/jolie
the term corresponding to the condition is expected to be on top of the stack. Then
an assertion that says the condition term is boolean is written. Afterwards the body is
processed using one of the other overloads of the visitor. These steps can be repeated
in case of existence of nested conditional statements. In the end of the method the else
branch body of the very first if is processed if it is present. There is also an important note
that the conditional statement does not impose any other direct type restrictions besides
the condition term that is confirmed by the mentioned typing rule. Other implemented
nodes can be seen in the source mentioned above.

The Jolie verifier takes some input for processing. Let us consider a simple piece of
Jolie code of Figure 3 with a conditional statement.

In the case everything works, none of the typing rules are violated. Z3 agrees with
the opinion and results in 'sat', that means the program state is satisfiable. Figure 5 lists
the SMT statements representing the condition processing.

The first assertion is made based on an expression type determination: the expression
\( a > b \) is boolean. The second one is imposed by the typing rule: the condition expression
must be boolean. In this case there is no contradiction between the two assertions.

If the condition is replaced with some other expression the typing rule may be
violated. The corresponding example of incorrect conditional expression is shown in
Figure 4 and the constructed SMT statements for the example are given in Figure 6.

In the case everything works, none of the typing rules are violated. Z3 agrees with
the opinion and results in 'sat', that means the program state is satisfiable. Figure 5 lists
the SMT statements representing the condition processing.

The first assertion is made based on an expression type determination: the expression
\( a > b \) is boolean. The second one is imposed by the typing rule: the condition expression
must be boolean. In this case there is no contradiction between the two assertions.

If the condition is replaced with some other expression the typing rule may be
violated. The corresponding example of incorrect conditional expression is shown in
Figure 4 and the constructed SMT statements for the example are given in Figure 6.
Now the contradiction between the assertions is notable. The checker decided the expression to be an integer, which is correct. But the restriction on a condition type from the typing rule simply contradicts the actual type. Consequently Z3 results in 'unsat'. This means the assertions representing program’s typing are unsatisfiable and incorrect in terms of the considered static type checking analysis.

5. Evaluation

The question of how to prove correctness of verification tools has always been widely discussed. How can we be sure that the output of such tool is correct? It can be poorly written, or the hardware could malfunction. However, in most cases we tend to trust verification tools, and in our project we have to make sure that this tool is as trustworthy as any other. The general solution is testing. Verification of the correctness the code being written was continuously performed during the development process. The Jolie Team created a collection of examples of Jolie programs. The verification results of some of them are presented in this section.

5.1. An unsatisfiable model

The overall purpose of the type checker is to find inconsistency in (assumed) type usage. The program listed in Figure 7 is the most basic example of a program with inconsistent types. The variable \textit{myInt} is assigned an integer first, and then a string. The current design of the type checker disallows this behavior.

```
main {
    myInt = 15;
    myInt = "fifteen"
}
```

Fig 7. Jolie code

```
(declare-const myInt Term)
(declare-const $$\_\_\_term\_id\_4 Term)
(assert (hasType $$\_\_\_term\_id\_4 int))
(assert (sameType myInt $$\_\_\_term\_id\_4))
(assert (hasType myInt int))
(declare-const $$\_\_\_term\_id\_10 Term)
(assert (hasType $$\_\_\_term\_id\_10 string))
(assert (sameType myInt $$\_\_\_term\_id\_10))
(assert (hasType myInt string))
```

Fig 8. Z3 code corresponding to Figure 7

The resulting set of SMT theorems is listed in Figure 8.

The model is unsatisfiable. Assertions on the lines 4-6 restrict type of \textit{myInt} to integer, whereas assertions on the lines 9-11 ensure that the same variable should be of type string. These assertions cannot be evaluated to be true in the same model. Therefore the program is considered ill-typed.

\footnote{https://github.com/jolie/examples}
5.2. A satisfiable model

In case everything in the program code is correct in terms of type consistency, the type checker should evaluate the resulting SMT model as satisfiable. It also should ignore cases that have not being processed properly yet, without giving any false positives. The program listed in Figure 9, in fact, an inconsistency in types usage. The line 8 reassigns a variable to be of type integer, whereas at the line 5 the same variable was introduced as a variable of type string. However, as long as this assignment include a statement with a dynamic key, the type checker ignores it. The reason for this is inability to determine which variable this path will point to at the moment of execution.

```plaintext
1 main
2 {
3     key = "cat";
4     animals.cat = "I am a cat";
5     animals.(key) = 13
6 }
```

Fig 9. Jolie code with dynamic key

The resulting set of SMT assertions is listed in Figure 10. The workaround for the dynamic keys issue can be seen at Lines 20 and 21. Any time a variable is used in order to construct another variable path, the whole Term is getting a unique identifier marked with the DYNAMIC_PATH substring. This way it will not interfere with any other assertion, thus not affecting the overall model satisfiability.

```plaintext
(declare-const key Term)
(declare-const __term_id_4 Term)
(assert (hasType __term_id_4 string))
(assert (sameType key __term_id_4))
(assert (hasType key string))
(declare-const __term_id_5 Term)
(declare-const animals Term)
(declare-const animals.cat Term)
(declare-const __term_id_10 Term)
(assert (hasType __term_id_10 string))
(assert (sameType animals.cat __term_id_10))
(assert (hasType animals.cat string))
(declare-const __term_id_11 Term)
(declare-const animals.DYNAMIC_PATH__term_id_14 Term)
(declare-const __term_id_19 Term)
(assert (hasType __term_id_19 int))
(assert (sameType animals.DYNAMIC_PATH__term_id_14 __term_id_19))
(assert (hasType animals.DYNAMIC_PATH__term_id_14 int))
```

Fig 10. Z3 code corresponding to the Jolie code of Figure 9
6. Conclusions and future works

Jolie is the first programming language specifically oriented to the microservice architecture. It has been shown how software attributes such as extensibility, modifiability and consistency can significantly benefit from a migration into the microservice paradigm [7, 5]. Projects run by our team demonstrated the efficacy of the paradigm and of the Jolie programming language in the field of ambient intelligence and smart buildings [29, 30]. Social networks implementation would also benefit from a reorganization of the software architecture [16]. Local projects, and beyond that a number of projects worldwide involving the use of Jolie, would immensely benefit from a fully stable implementation of the Jolie Static Type Checker.

Static type checking allows compilers to identify certain programming mistakes (that violate types) at compile time, i.e. before actually running the program. Therefore a vast number of trivial bugs can be caught and fixed at a very early stage of the software life-cycle. In this paper we described JSTC, a static type checker for the Jolie programming language which natively supports microservices. A static type system for the language has been exhaustively and formally defined on paper, but so far still lacked an implementation. We introduced our ongoing work on a static type checker and presented some details of the implementation. The type checker prototype, at the moment, consists of a set of rules for the type system expressed in SMT Lib language. The actual implementation covers operations such as assignments, logical statements, conditions, literals and comparisons.

JSTC is already able to validate programs, as it has been shown in this paper. However, it works with certain assumptions. The main assumption is that programs do not contain implicit type casts. The Jolie language allows implicit type casts, however, their behavior is very complex. Handling such situations is an open issue left for future development and future versions. Two other major issues have not been addressed.

Variable types can be changed at runtime. This strictly depends on the approach that has been chosen. Generally, static typing guarantees that a variable has a type that cannot be changed after declaration or assignment. However, Jolie allows this operation. We need to determine which behavior we expect from the type checker, thus deciding how to process type changes.

Implicit type casts in Jolie are ambiguous. This is a major problem, and further research is required in order to find a solution. While Jolie allows implicit type casts, sometimes the result of a cast is not obvious. For example, casting a negative Integer to Boolean will result in a False. This is an unexpected behavior when compared to other programming languages. There may be a solid rationale for this, however, we need to investigate all cases and make sure that the type checker works accordingly to the Jolie actual behavior, and not to the expected one.

JSTC future releases will need to be validated in real-life applications. The plan is to use the Jolie programming language and the type checker as a basis for the development of future research projects, the same way was done in [29] and [30]. Potential application scenarios are cognitive architecture [32], automotive systems [8] and smart houses [23].

Аннотация. Статическая верификация исходного кода программы является важным элементом надежности программного обеспечения. Под верификацией предполагается доказательство соответствия поведения программы ее спецификации. Во многих языках программирования используется как статическая, так и динамическая проверка типов. Таким образом, статический тайп-чекер старается проверить все возможное во время компиляции, а динамический проверяет оставшиеся. На данный момент язык программирования Jolie имеет динамическую систему типов, что позволяет обнаруживать ошибки только во время выполнения программы. Статическая система типов для языка была формально определена на бумаге, но пока не реализована. В этой статье мы представляем прототип статического тайп-чекера для языка программирования Jolie (JolieStaticTypeChecker или JSTC), основанный на SMT-решателе. Мы описываем базовую теорию, необходимую для реализации тайп-чекера, саму реализацию, а также процесс статического анализа программы. Статья публикуется в авторской редакции.
